- **Fast Fourier Transform (FFT):**
 - Radix-2 Decimation-in-Time (DIT)
 - Radix-2 Decimation-in-Frequency (DIF)
- **Conclusion:** FFT Complexity Analysis

- Let's start with a Continuous-time periodic signal $x(t)$ with period T_0 :

$$x(t + T_0) = x(t), \quad \omega_0 \triangleq \frac{2\pi}{T_0}.$$

- We have learnt the Continuous Time Fourier Series (CTFS) representation is:

CTFS Pair

$$x(t) = \sum c_k e^{jk\omega_0 t}$$

$$c_k = \frac{1}{T_0} \int_{T_0} x(t) e^{-jk\omega_0 t} dt$$

We are now interested in a representation for discrete signals. We can sample $x(t)$ to get a discrete signal $x[n]$.

- Sample $x(t)$ uniformly with sampling period T_s .
- Assume T_0 is captured by N samples:

$$T_0 = NT_s \quad (N \in \mathbb{Z}^+).$$

- The purely discrete sequence $x[n]$ is defined as:

$$x[n] \triangleq x(nT_s), \quad n \in \mathbb{Z}.$$

- Thus $x[n]$ is inherently **N -periodic**:

$$x[n + N] = x[n].$$

Impulse-Train Representation of Sampling

- We can represent the sampled signal mathematically using an impulse train (aka Dirac comb).
- Multiplying the continuous signal $x(t)$ with the impulse train $p(t)$ gives us the sampled signal $x_p(t)$.
- Each sample $x[n]$ is weighted by a Dirac delta function at time nT_s .

Impulse train $p(t) = \sum \delta(t - nT_s)$.

Sampled signal $x_p(t) = x(t)p(t)$.

$$x_p(t) = \sum_{n=-\infty}^{\infty} x(nT_s) \delta(t - nT_s) = \sum_{n=-\infty}^{\infty} x[n] \delta(t - nT_s).$$

Now let us find the CTFS of the sampled signal $x_p(t)$.

- Let c_k denote the CTFS coefficients of the T_0 -periodic sampled signal $x_p(t)$:

$$x_p(t) = \sum_{k=-\infty}^{\infty} c_k e^{jk\omega_0 t}, \quad c_k = \frac{1}{T_0} \int_{T_0} x_p(t) e^{-jk\omega_0 t} dt.$$

- Substitute $x_p(t) = \sum_{n=-\infty}^{\infty} x[n]\delta(t - nT_s)$ into the analysis equation:

$$\begin{aligned} c_k &= \frac{1}{T_0} \int_{t_0}^{t_0+T_0} \left(\sum_{n=-\infty}^{\infty} x[n]\delta(t - nT_s) \right) e^{-jk\omega_0 t} dt \\ &= \frac{1}{T_0} \sum_{n=0}^{N-1} x[n] \int_{t_0}^{t_0+T_0} \delta(t - nT_s) e^{-jk\omega_0 t} dt \\ &= \frac{1}{T_0} \sum_{n=0}^{N-1} x[n] e^{-jk\omega_0 nT_s} \\ &= \frac{1}{T_0} \sum_{n=0}^{N-1} x[n] e^{-j\frac{2\pi}{N}kn}. \end{aligned}$$

We can take $t_0 = -\frac{T_s}{2}$, so $\delta(t - nT_s)$ is non-zero in $[t_0, t_0 + T_0]$ only for $n = 0, 1, 2, \dots, N-1$.

- Examine the exponent in c_k :

$$\begin{aligned}c_{k+N} &= \frac{1}{T_0} \sum_{n=0}^{N-1} x[n] e^{-j \frac{2\pi}{N} (k+N)n} \\&= c_k \underbrace{e^{-j 2\pi n}}_{=1} = c_k\end{aligned}$$

- The contiguous frequency coefficients are N -periodic!
- Only N unique frequency values** exist before the spectrum repeats.
- Leads to the N -point Discrete Fourier Transform.

- The N -point **discrete Fourier transform (DFT)** of a length- N sequence $\{x[n]\}_{n=0}^{N-1}$ is defined simply as a scaled version of one period of the unique c_k components:

Discrete Fourier Transform (DFT)

$$X[k] \triangleq \sum_{n=0}^{N-1} x[n] e^{-j \frac{2\pi}{N} kn}, \quad k = 0, 1, \dots, N-1$$

- Thus, the relationship is $c_k = \frac{1}{T_0} X[k]$.

- We cannot simply use the CTFS synthesis equation to recover our signal:

$$x(t) = \sum_{k=-\infty}^{\infty} c_k e^{jk\omega_0 t}$$

- This equation evaluates to the continuous-time impulse train $x_p(t)$, not the purely discrete sequence $x[n]$ which we desire.

- We cannot simply use the CTFS synthesis equation to recover our signal:

$$x(t) = \sum_{k=-\infty}^{\infty} c_k e^{jk\omega_0 t}$$

- This equation evaluates to the continuous-time impulse train $x_p(t)$, not the purely discrete sequence $x[n]$ which we desire.
- However, there is a general pattern in transforms from our experience:
 - **Forward Transform** (Analysis) usually uses $e^{-j\cdots}$ (e.g., $e^{-jk\omega_0 t}$)
 - **Inverse Transform** (Synthesis) usually uses $e^{+j\cdots}$ (e.g., $e^{+jk\omega_0 t}$)
- Let's apply this intuitive pattern to derive an explicit recovery formula for $x[n]$ using $e^{+j\cdots}$.

- Multiply both sides of the DFT by $e^{j\frac{2\pi}{N}kn}$ and sum over k :

$$\begin{aligned}\sum_{k=0}^{N-1} X[k] e^{j\frac{2\pi}{N}kn} &= \sum_{k=0}^{N-1} \left(\sum_{m=0}^{N-1} x[m] e^{-j\frac{2\pi}{N}km} \right) e^{j\frac{2\pi}{N}kn} \\ &= \sum_{m=0}^{N-1} x[m] \left(\sum_{k=0}^{N-1} e^{j\frac{2\pi}{N}k(n-m)} \right)\end{aligned}$$

- Evaluate the inner summation using the geometric series sum formula. For $n \neq m$:

$$\sum_{k=0}^{N-1} \left(e^{j\frac{2\pi}{N}(n-m)} \right)^k = \frac{1 - e^{j2\pi(n-m)}}{1 - e^{j\frac{2\pi}{N}(n-m)}} = \frac{1 - 1}{1 - e^{j\frac{2\pi}{N}(n-m)}} = 0$$

- And for $n = m$, the summation simply evaluates to:

$$\sum_{k=0}^{N-1} e^0 = N \implies \sum_{k=0}^{N-1} e^{j \frac{2\pi}{N} k(n-m)} = \begin{cases} N & n = m \\ 0 & n \neq m \end{cases}$$

- Applying this to the previous equation, all terms in the outer sum become zero except when $m = n$:

$$\sum_{k=0}^{N-1} X[k] e^{j \frac{2\pi}{N} kn} = x[n] \cdot N$$

- Rearranging for $x[n]$ gives the **Inverse DFT (IDFT)**:

Inverse Discrete Fourier Transform (IDFT)

$$x[n] = \frac{1}{N} \sum_{k=0}^{N-1} X[k] e^{j \frac{2\pi}{N} kn}, \quad n = 0, 1, \dots, N-1$$

Periodic-Signal View

$$X(j\omega) = 2\pi \sum_{m=-\infty}^{\infty} a_m \delta(\omega - m\omega_0)$$
$$\omega_k = \frac{m\omega_s}{N} = k\omega_0$$

- A continuous-time periodic signal has a **line spectrum**: only harmonic spikes at integer multiples of ω_0 .
- This is the same periodic-recovery viewpoint revisited later in Sampling: if $N = T_0/T_s$, then $\omega_s = N\omega_0$.
- Hence $\omega_k = \frac{k\omega_s}{N} = k\omega_0$, so the DFT bins land **exactly on the harmonic lines**.
- That is why the DFT isolates the N unique Fourier-series coefficients so cleanly in the periodic case.

one period of samples

N unique coeffs

What about Aperiodic Signals?

But does DFT only apply to periodic signals? What if the signal is aperiodic?

- Now switch to the practical **finite-capture** setting used in Sampling's "Connection to the DFT" section: an aperiodic signal $x(t)$ observed only over a finite interval T_0 .
- Uniformly sampling this yields a finite-length sequence $x[n]$ that is nonzero only for $0 \leq n \leq N - 1$.
- Unlike the periodic case, the associated spectrum is **continuous** rather than isolated Fourier-series spikes.
- Using the pulse train sampling method with sampling period T , we can represent the sampled signal as:

$$x_p(t) = x(t)p(t) = \sum_{n=-\infty}^{\infty} x[n]\delta(t - nT) = \sum_{n=0}^{N-1} x[n]\delta(t - nT)$$

First take the CTFT of the sampled impulse train:

CTFT of the sampled signal

$$X_p(j\omega) = \sum_{n=-\infty}^{\infty} x[n]e^{-j\omega nT}$$

- This formula is written in the physical frequency variable ω and is exactly the repeated sampled-spectrum picture we will revisit in Sampling.
- Now compress the frequency axis by the sampling period and reuse the symbol, i.e. apply the mapping $\omega T \mapsto \omega$.
- Under that relabeling, the same spectrum becomes the **Discrete-Time Fourier Transform (DTFT)**:

$$X(e^{j\omega}) \triangleq X_p(j\omega)|_{\omega T \mapsto \omega} = \sum_{n=-\infty}^{\infty} x[n]e^{-j\omega n}.$$

- For our length- N capture,

$$X(e^{j\omega}) = \sum_{n=0}^{N-1} x[n]e^{-j\omega n}.$$

Period of the DTFT

The value of $X(e^{j\omega})$ repeats every 2π :

$$\begin{aligned}e^{-j(\omega+2\pi)n} &= e^{-j\omega n} e^{-j2\pi n} \\ &= e^{-j\omega n}\end{aligned}$$

$$X(e^{j(\omega+2\pi)}) = X(e^{j\omega})$$

How to Read One Period

- Any interval of width 2π contains one complete DTFT period.
- A common principal interval is $[-\pi, \pi]$.
- $[\pi, 2\pi]$ is the shifted copy of $[-\pi, 0)$.

Before $\omega T \mapsto \omega$, the physical sampled spectrum has period

$\omega_s = \frac{2\pi}{T}$; we revisit that view in Sampling.

The Path to the DFT (Aperiodic Signals)

- In Sampling's "Connection to the DFT" section we showed that the DFT simply samples the CTFT of the impulse train:

$$X[k] = X_p\left(j\frac{k\omega_s}{N}\right), \quad \omega_s = \frac{2\pi}{T}.$$

- Under the same mapping $\omega T \mapsto \omega$, this becomes the normalized DTFT statement:

$$X[k] = X(e^{j\omega})\Big|_{\omega=\frac{2\pi}{N}k}.$$

- So the N -point DFT takes N **evenly spaced samples** over one repeated spectrum.
- For even N , bins $k = 0, \dots, \frac{N}{2}$ run from dc to the highest positive frequency, while bins $k = \frac{N}{2} + 1, \dots, N - 1$ run from large negative frequencies back toward dc after wrapping.

Zero-Padding for Increased Frequency Resolution

- **Zero-Padding:** For an aperiodic $x[n]$ of length N , we can artificially append zeros to define it over a total length $M \geq N$.
- Taking the M -point DFT samples the same continuous DTFT spectrum $X(e^{j\omega})$, but at a much finer resolution of $2\pi/M$ over that same wrapped 2π frequency axis.

$x[n]$ padded
